User Guides and Licenses and Manage Serial. Adobe Acrobat Pro DC.To allow successful folding and randomization of single domain polypeptides to yield proteins of correct size and stability, the efficiency of translation termination is the one determining factor, in addition to the rate of incorporation of the aminoacyl-tRNAs. We have previously shown that the translation termination efficiency is higher for sequences that contain a long run of four hydrophobic amino acids in the middle of the coding region. These include the stop signal, UGA, which is the least stable codon, and UCU, which is more stable than UAA (E9 and G1, respectively). We also found that the addition of dDcm, which is stable in the wobble position of UGA and UCU, improves the translation termination efficiency of these codons. We have now found that dDcm interacts with the ribosome and binds to the ribosome at the region immediately adjacent to the anti-Shine-Dalgarno site. We will therefore explore the function of this interaction in termination by chemical cross-linking, and determine the ribosome structure in a near-atomic resolution model. We plan to look for additional compounds that interact with the ribosome in a similar way. If these compounds can be found, they should aid in the crystallization of the ribosome. We will also search the ribosome for additional long runs of hydrophobic amino acids, and explore their function as translation termination signals. Lastly, we will determine whether our combined findings can be extended to other codons.
